

Programming Thinking

Session 3

Pepe García jgarciah@faculty.ie.edu

SCHOOL OF
SCIENCE &
TECHNOLOGY

Plan for this session

- Python basic datatypes

Plan for this session

- Python basic datatypes
- Variables

Plan for this session

- Python basic datatypes
- Variables
- Operators

Plan for this session

- Python basic datatypes
- Variables
- Operators
- Basic functions

Datatypes tell Python how we want to use the data. There are several primitive data types in Python such as **bool**, **int**, **str**, **float**.

Integers

Integers (or ints) represent whole numbers. We create them by using their numeric representation directly.

1

234

432432

Integers

Integers (or ints) represent whole numbers. We create them by using their numeric representation directly.

1

234

432432

Demo

Floating point numbers

Floats represent numbers that have a fractional part. We use a dot to separate the integer and fractional parts:

3.14

1.0

33.33

Floating point numbers

Floats represent numbers that have a fractional part. We use a dot to separate the integer and fractional parts:

3.14

1.0

33.33

Demo

Strings

Strings are used for textual representation. They can be created using either double or simple quotes.

'this is a string'

"this is another string"

Strings

Strings are used for textual representation. They can be created using either double or simple quotes.

```
'this is a string'
```

```
"this is another string"
```

Demo

Why can one use either double or single quotes? why just not agree on one of them?

Booleans

Booleans represent truthiness. There are only two values in for the bool type in Python: **True** and **False**

True

False

Booleans

Booleans represent truthiness. There are only two values in for the bool type in Python: **True** and **False**

True

False

Demo

Getting the type of a value

We can always get the type of a value using the **type(value)** function

```
type("patata")
```

Getting the type of a value

Practice

Inside Spyder, check what's the type of the following expressions:

- `"there is some text here"`
- `1`
- `True`
- `44.4`
- `'true'`
- `'False'`
- `2`
- `'33.3'`

Operators are symbols in the language that perform different kinds of computations on values

They're **binary**, they will operate on two values.

Arithmetic Operators

symbol	meaning
+	sum
-	subtraction
*	multiplication
/	division
**	exponentiation
//	floored division
%	modulus

Rules of precedence

- Parentheses

Demo

Rules of precedence

- Parentheses
- Exponentiation

Demo

Rules of precedence

- Parentheses
- Exponentiation
- Multiplication/Division

Demo

Rules of precedence

- Parentheses
- Exponentiation
- Multiplication/Division
- Sum/Substraction

Demo

Rules of precedence

- Parentheses
- Exponentiation
- Multiplication/Division
- Sum/Substraction
- when operators have the same precedence, evaluate left to right

Demo

String operators

Sum and multiplication operators work on strings too. They're used to concatenate and multiply strings, respectively.

String operators

Sum and multiplication operators work on strings too. They're used to concatenate and multiply strings, respectively.

Demo

Variables are names that point to values in Python. We declare them using the assignment operator (=).

```
variable_name = "value"
```

Naming variables

It's important to be as descriptive as possible when naming variables
There are some naming rules we should obey

Naming variables

It's important to be as descriptive as possible when naming variables
There are some naming rules we should obey

Rules

- variable names can't start with a number
- variable names can't contain special characters such as `!`, `@`, `.`
- Can't be one of the reserved words

Reserved words

and	del	from	None	True
as	elif	global	nonlocal	try
assert	else	if	not	while
break	except	import	or	with
class	False	in	pass	yield
continue	finally	is	raise	
def	for	lambda	return	

Mutability

In Python variables are mutable. This means that we can change their value at any time

```
name = "Pepe"  
print(name)
```

```
name = "Jose"  
print(name)
```

Converting values

There are some times when we need to convert a value from one type to another.

We use the **int()**, **bool()**, **str()**, and **float()** functions for that

Converting values

There are some times when we need to convert a value from one type to another.

We use the **int()**, **bool()**, **str()**, and **float()** functions for that

```
int('23')
```

```
bool(1)
```

```
bool(0)
```

```
str(True)
```

```
float("3.2")
```

Printing output

One can print output using the **print()** function

There is a handy function **input()** that allows us to capture input from the user

```
name = input("Tell me your name: ")  
  
print("hello, " + name)
```

- Datatypes (int, float, bool, str)

Recap

- Datatypes (int, float, bool, str)
- Variables (naming, mutability)

Recap

- Datatypes (int, float, bool, str)
- Variables (naming, mutability)
- Operators (arithmetic, precedence, string operators)

- Datatypes (int, float, bool, str)
- Variables (naming, mutability)
- Operators (arithmetic, precedence, string operators)
- Converting values

Recap

- Datatypes (int, float, bool, str)
- Variables (naming, mutability)
- Operators (arithmetic, precedence, string operators)
- Converting values
- User input

Exercises

- 1 Create a program that calculates the total number of seconds in an hour
- 2 How does the following expression evaluate?

`2 + (3 + 4) + (5 * 33 ** 34)`

- 3 Create a program that asks the user for their age and their mother's age and calculate the age difference
- 4 What are the results and result types of the following expressions?
think it yourself, do not use the Python console for this

`3 * 5 * 2`

`3 / 11`

`3 // 11`

`25 % 2`

- 5 Make the following expressions work (use Python console for this one)
`3 + "3" 'there are' + 4 ' dogs barking'`
